

Do People Really Become More Conservative as They Age?

Abstract

Folk wisdom has long held that people become more politically conservative as they grow older, though several empirical studies suggest political attitudes are stable across time. Utilizing data from the Michigan Youth-Parent Socialization Panel study, we analyze attitudinal change over a major portion of the adult lifespan. We document changes in party identification, self-reported ideology, and selected issue positions over this time period and place these changes in context by comparing them with contemporaneous national averages. Consistent with previous research but contrary to folk wisdom, our results indicate that political attitudes are remarkably stable over the long-term. In contrast to previous research, however, we also find support for folk wisdom: On those occasions when political attitudes do shift across the lifespan, liberals are more likely to become conservatives than conservatives are to become liberals, suggesting that folk wisdom has some empirical basis even as it overstates the degree of change.

Keywords: attitude change, liberals, conservatives, ideology, socialization

Supplementary material for this article is available in the appendix in the online edition.

Replication files are available in the JOP Data Archive on Dataverse

(<http://thedata.harvard.edu/dvn/dv/jop>).

One of the most widespread generalizations among social scientists and the lay public is that people become more conservative as they grow older (Glenn 1974). This belief is captured in the well-known aphorism that “if you are not a liberal at 20 you have no heart and if you are not a conservative at 30 you have no brain,” variants of which date from at least the time of the French Revolution. Voting patterns seem to confirm the relationship between aging and conservatism. For example, exit polls suggest just 37% of 18 to 29-year-old voters cast a ballot for Donald Trump in the 2016 presidential election, compared to 43% of 30 to 44 year-old voters, and 53% of those over 45. Despite the broad acceptance of this folk wisdom, in the scholarly literature the theoretical foundations linking aging to shifts in political attitudes are somewhat inconsistent and empirical support is, at best, mixed. Our goal in this article is to examine the theoretical models for expecting aging to lead to a more conservative political orientation and to provide a robust empirical test of this relationship.

Theory and Literature

Why is aging so often expected to produce a conservative shift? Aspects of aging include psychological aging, physiological aging, social aging, biological aging, economic aging, and aging in and of itself. A theoretical basis for expecting a rightward drift in political views can be constructed from nearly all of these. Psychological and physiological age-related changes, for example, include increasing self-discipline, preference for order, uncertainty avoidance, the capacity to remember emotionally laden stimuli, and alterations in neural structures (Dennis et al. 2008; Jost et al. 2007; St. Jacques, Florin, and Cabeza 2009). All of these can plausibly be connected to personality characteristics, such as greater conscientiousness and diminished openness to new experiences, frequently associated with conservatism (Mondak 2010; Gerber et al. 2010; Soto et al. 2011; Srivastava et al. 2003). Such psychological and personality changes

could lead to endorsement of more authoritarian and traditional values and norms (Cornelis et al. 2009) and perhaps even higher levels of prejudice (Henry and Sears 2009).

Social aging refers to changes in patterns of social interactions across the life course. From the 20s to the 50s social patterns are often dominated by increasing familial connections, while retirement from the workforce in the 60s may be accompanied by a rapid decline in overall social interactions. These sorts of changes in social opportunities and obligations could affect values and approaches to life that are related to politics. For example, evidence suggests that people in middle age care more about their work, their responsibilities, and their family and these tendencies may direct attention toward more immediate, personal concerns (Angel and Settersten 2013; Srivastava et al. 2003). Such a growing focus on immediate, personal matters could facilitate a pattern consistent with folk wisdom, as middle aged individuals lose some of the idealism might have been present prior to the assumption of family and work responsibilities (Glenn 1974).

Changes in economic status also frequently accompany aging. Financial resources tend to grow with time spent in the workforce and accumulate as a career gathers momentum. An increase in resources during the movement into middle age might lead some to develop greater appreciation for a stable, predictable, secure society and also to embrace laissez faire stances on taxation and redistribution (Angel and Settersten 2013). Retirement can also bring a shift in economic status, a change that may have important implications for political attitudes and behavior. For example, there is good evidence that the importance of Social Security to the financial well-being of senior citizens is an important motivator of their political attitudes and actions (Campbell 2002).

Biological aging occurs throughout the life course and we already mentioned the gradual shifts in neural functioning that could be connected to conservatizing tendencies. On the other hand, major and often rapid late-in-life changes like health declines can dramatically affect lifestyle and motility (Sears 1981). Unlike the other effects of aging we have discussed, serious health needs may shift some political views to the left. Though we do not know of any empirical evidence on this point, as health deteriorates in advanced years the need for assistance from others, including the government, increases and could lead to support for interventionist, redistributive healthcare policies.

Yet another aspect of aging is simply the passage of the years themselves. Even if an individual's psychological, social, economic, and health situations were somehow to remain constant, the fact remains that every year brings more experiences. This means that each subsequent event is mathematically an inevitably smaller proportion of the summation of life's previously accumulated experiences. As a result, the passage of the years may bring what appears to be a greater reluctance to change in light of new events and a greater weddedness to what has come before (Glenn 1974).

In sum, aging brings a complicated web of changes but theoretical reasoning and previous scholarship suggests that on balance aging can be expected to push many toward the political right. However, there are reasons to be cautious about over-generalizing aging's impact on political drift. First, individual variation in the components of the aging process is enormous. For example, certainly not all people see their financial status improve as their lives unfold. Second, linearity should not be assumed; as mentioned above, social connections and exposures tend to increase into middle age but then decrease after retirement with similar patterns possible for financial status as well as other variables (see Danigelis, Hardy, and Cutler 2007). Third, the

case for expecting a conservative shift is not equally strong with regard to all categories of political issues, making it possible for the results of aging to be different for stances on social as opposed to economic issues.

The most important reason for caution, however, may be that two very different conceptualizations of conservatism can be found in the literature on politics and aging. The first is the classic Burkean formulation entailing active endorsement of policies designed to promote the existing social order. This means favoring policies supporting that social order and countering threats to it by norm violators and out-groups. The second meaning of conservatism is less concerned with the substantive policy positions than the degree to which an individual clings to beliefs. Reluctance to change is a distinct view of conservatism in that it suggests someone who settles into increasingly inflexible left-of-center stances is also demonstrating conservatism in a certain sense of the word (for a discussion of these two aspects of conservatism, see Jost et al. 2003). Depending upon which conceptualization of conservatism is being employed, quite different answers regarding the aging-conservatism connection may very well be produced.

To add to the confusion, empirical work on the relationship between aging and political orientations varies depending upon disciplinary focus. Political scientists have largely explored the degree of stability of political attitudes with only minimal attention to the direction of any movement that does occur (e.g., Campbell et al. 1960; Converse 1964; Jennings and Markus 1984). Scholars in sociology, psychology, and gerontology, however, have been more interested in the direction of movement—that is, in whether people generally move toward more conservative postures (e.g., Cornelis et al. 2009; Danigelis, Hardy, and Cutler 2007).

Turning first to the political science literature, at least five prevailing theories are in evidence. The lifelong persistence model, derived primarily from the work of Campbell et al.

(1960), suggests political attitudes result from socialization early in life and then persist throughout the lifespan despite new political shocks and information. Though primarily applied to party identification, the lifelong persistence model also provides testable hypotheses for issue attitude change and related concepts.

The impressionable years model argues that young adults, roughly between the ages of 18 and 26, are susceptible to attitudinal change but that thereafter attitudes crystalize and become increasingly immune to new information as the years go on (Alwin, Cohen, and Newcomb 1991; Alwin and Krosnick 1991; Newcomb 1943; Newcomb et al. 1967; Jennings and Markus 1984; Jennings and Niemi 1981; Markus 1979; Niemi and Jennings 1991; Sears and Funk 1999; Stoker and Jennings 2008). In sum, the impressionable years model suggests people are pliable in early adulthood but relatively stable after that (Dinas 2013).

Other models allow for the possibility of more change throughout the lifespan. The party loyalty model holds that individuals have no stable or fixed opinions separate from their partisan loyalty. In other words, this model implies that after controlling for party identification, attitudes are correlated as if individuals were expressing issue positions more or less at random (see Achen and Bartels 2016; Page and Shapiro 2010; Zaller 1992).

The lifelong openness model suggests that attitudes remain equally responsive to new information and events throughout the lifespan. This model is most succinctly presented by Franklin and Jackson (1983) and Franklin (1984) who found that partisan identification was responsive to the ever-changing policy orientations of the Democratic and Republican parties. Presumably, the direction of the change would depend on the nature of the evolving political environment.

The running tally model is a rational choice approach to political learning primarily developed by Fiorina (1981) and expanded upon by Gerber and Green (1998) and Achen (2002). This approach suggests that people routinely update their attitudes based on retrospective (Fiorina 1981; Gerber and Green 1998) or prospective (Achen 2002) evaluations of the political environment. Similar to the lifelong openness model, the running tally model allows for attitudes to fluctuate throughout the lifespan. Contrary to the lifelong openness model, the running tally model accords a large role to prior attitudes and they are expected to continue to be factored into constantly accumulating “tallies.”

An interesting feature of all the models in the political science literature is that none are directional. In other words, none of them directly addresses the veracity of the claim that a conservative shift accompanies aging, except in the sense that no significant aging-related conservative shift is possible if orientations are completely stable through the years (lifelong persistence) or largely stable after an early and ephemeral period of flux (impressionable years). To put it another way, none of these models predicts or expects an inherent bias toward conservative rather than liberal change. In this sense the political science literature tends to focus on the degree rather than the direction of change with most of the results pointing toward a substantial amount of stability as aging occurs.

In contrast, on the basis of the changes accompanying aging, the literature in other disciplines displays significantly greater interest in the direction of change, with the common expectation and finding being that for a variety of politically-relevant issues the direction of change observed will be toward the right rather than the left (see Cornelis et al. 2009; Franssen, Dhont, and Van Hiel 2012; Kossowska, Jasko, and Bar-Tal 2012; Tilley and Evans 2014; Van

Hiel and Brebels 2011; Wilson 1973, though see Schwadel and Garneau 2014). As such, these results seem to support folk wisdom.

In summary, the existing literature exhibits no shortage of theoretical models linking aging to political attitudes. Broadly speaking those models focus on direction or stability (but not both), and have discordant expectations. Direction focused theoretical frameworks, mainly developed outside political science, generally (but not uniformly) suggest that various aspects of the aging process (psychological aging, economic aging, etc.) support conventional wisdom in predicting a rightward drift over the lifespan. The bulk of stability focused models developed in political science argue for long-term stasis in political attitudes or at least partisanship throughout adulthood (lifelong persistence, impressionable years, party loyalty), though there are clearly counter-arguments for instability (lifelong openness, running tally). What might a coherent combination of all these disparate theoretical arguments look like? A reasonable synthesis is a model that predicts a general stability in political attitudes, at least once out of early adulthood, but allows for change and predicts that any such change is more likely to move in a conservative rather than a liberal direction. Such a synthesis clearly captures the dominant theoretical arguments relating to direction, while also incorporating political science work arguing for stability.

This model suggests a set of straightforward hypotheses: (1) Political attitudes will remain relatively stable across adulthood. (2) Over the long-term, any change in attitudes that does occur will more likely be to the political right rather than the political left. Finding these patterns would support our synthesized model. To the best of our knowledge, these hypotheses have never been simultaneously tested. If an empirical analysis fails to support either hypothesis—that is, if attitudes are unstable and move equally in both directions—it would

suggest two of the models championed in political science (lifelong openness, running tally) are the stronger theoretical accounts of the link between aging and political attitudes. A clear move to the left would constitute an empirical result with very little theoretical basis.

The Challenges of Theory Testing

A huge obstacle to empirically assessing the relationship between aging and political attitudes is data availability. Ideally, testing hypotheses on aging and political orientations requires a data set containing longitudinal information on political views across the adult lifetime for many people in many different cohorts. Yet long-term longitudinal data sets for even a single cohort are rare, which is undoubtedly why most research has used cross-sectional data (Cornelis et al. 2009; Danigelis, Hardy, and Cutler 2007; Franssen, Dhont, and Van Hiel 2012; Glenn 1974; Grant et al. 2001; Kossowska, Jasko, and Bar-Tal 2012; Schwadel and Garneau 2014; Searing, Wright, and Rabinowitz 1976; Van Hiel and Brebels 2011).

The problem with using cross-sectional data is that they are obviously ill-equipped to identify life-cycle effects. Just because older people are more conservative than younger people at any given time does not mean that people have become more conservative as they age. After all, many factors other than the process of aging could account for persistent positive cross-sectional correlations between age and conservatism. Perhaps liberals tend to pass away at a younger age than conservatives. Perhaps liberals are more likely to quit answering survey requests as they get older. Perhaps society itself became more liberal over time (for evidence that this may indeed be the case, see Schwadel and Garneau 2014), making it appear as though individuals themselves changed when in fact individuals were largely static while the world evolved around them. Or perhaps over-time changes occurred in a third variable (e.g., increases in mean years of education and especially in college attendance) that is related both to political

beliefs and to age, that then might give the impression of growing conservatism when it is really just the case that the older people in a cross-section were less likely to have, say, extended education. In short, standard cross-sectional data confound aging effects with period effects (for a thorough discussion of these and related issues, see Firebaugh 1997; Yang and Land 2013).

In the absence of longitudinal data, several scholars have turned to synthetic or constructed cohort analysis (e.g., Alwin 1994). Advantages accrue to such an approach but it typically relies on the assumption that the only causes of attitudinal change within a cohort are the result of intra-cohort aging/learning and not attrition from the cohort (Dangelis, Hardy, and Cutler 2007). The assumption of no attrition would be less concerning except for recent evidence of systematic differences in mortality rates for liberals and conservatives (see Pabayo, Kawachi, and Muenni 2015; Subramanian et al. 2009; Subramanian et al. 2010). So while cohort analyses have provided many useful insights, authoritatively adjudicating between life cycle and either generational or period effects requires real longitudinal data, preferably spanning several decades.

This reality has led some scholars to turn toward data that follows individuals across major portions of their lives. Such data are still not perfect because any given cohort may not be typical, meaning that results could have been much different with a cohort from an earlier or later time period. Still, the ability to see changes in a given cohort at multiple life stages is a real advantage and makes it possible to document political changes over the course of a lifetime for that cohort at least. One problem is that few data sets measure political beliefs for the same people during periods of time longer than a few years. To be more specific, as far as we are aware, only three publically accessible, long-term longitudinal data sets contain the information necessary to assess the degree and nature of political change over the course of a significant

portion of the life span: the Bennington Study, the Terman Study, and the Michigan Youth-Parent Socialization Study.

The Bennington Study began as an investigation of attitude change among approximately 500 students attending Bennington (VT) College—at that time an all-female institution—in the late 1930s. In 1960, 350 of the Bennington women were re-interviewed to see if the changes had persisted and then, in 1984, when most of the women were in their late 60s, 266 once again were re-interviewed. The items posed in these interviews included nine dealing with specific social and economic issue attitudes (for a valuable summary, see Alwin, Cohen, and Newcomb 1991).

The Terman Study began in the early 1920s when Stanford Psychologist Lewis Terman identified and tested approximately 1,500 intellectually gifted high-school students. Mail questionnaires were completed by an impressive number of the original participants in 1940, 1950, 1960, and 1977. Political information—usually only party identification and self-reported ideology—was not contained in the original data collection so the useful period covered is approximately 37 years, from about the time participants were in their early 30s till when they were approximately 70 years of age (for more details, see Sears and Funk 1999).

The dominant analytic approach in this literature correlates an individual's attitudes in previous waves with attitudes in subsequent waves, using either standard correlations, continuity coefficients, or test-retest statistics (see, for example, Sears and Funk 1999; Jennings, Stoker, and Bowers 2009). The central finding with regard to the effects of aging on political orientations is that a significant amount of stability in views is present.

Though variants of continuity coefficients are perfectly appropriate if the topic of interest is persistence, they only afford indications of the degree of change (in other words, of the extent to which views at, for example, age 25 correlate with the same person's views at age 40).

Surprisingly little attention in political science has been given to the direction of change as opposed to the degree of change (for a brief exception, see Sears and Funk 1999: 10). We should note in passing that some scholars have been interested in the distinct but related matter of changes in levels of political participation and interest (see, for example, Green and Shachar 2000; Walsh, Jennings, and Stoker 2004). When, as is the case in this article, the focus is on political preferences, the main area of scholarly concern has tended to be on changes in party identification, with ideology and individual issues getting much briefer attention. Stoker and Jennings (2008), for example, focused on changes over time in the link between party identification and issue positions, and Sears and Funk (1999) analyzed changes in issue salience.

The sample characteristics for both of these longitudinal data sets (females attending an exclusive college in the Northeast and extremely gifted high school students in California) urge caution when generalizing. Given the atypical nature of these two samples, we were attracted to the third longitudinal data set: the Michigan Youth-Parent Socialization Study (hereafter MSS). These data have been described in great detail in other work (see Jennings and Niemi 1981; Jennings et al. 2005) and afford a unique opportunity to study attitudinal change. The MSS was initiated by surveying 1,669 high school seniors and their parents in 1965. (We should note that, since in the mid-1960s many students would have dropped out of high school before their senior year, even this sample is certainly not perfectly representative). The study then re-interviewed those same people in 1973, 1982, and then again in 1997, when the researchers not only returned to the original youth cohort but also interviewed their children. We focus here on the individuals who were high school seniors in 1965 since they provided the most complete information, though even here data are not available across the entire time span of the survey. For example, ideological self-identification was not asked in 1965 though it was in the other three waves.

A total of 935 of the original respondents were re-interviewed in the final, mid-1997 wave, an impressive retention rate of 56% from the original pool. In 1997 about half of the interviews were face-to-face and half by telephone while the data from the three prior waves were mostly collected through face-to-face interviews. All interviews were conducted by the Survey Research Center of the University of Michigan (see Jennings, Stoker, and Bowers 2009 for more details). The nature of this data set provides advantages for studying change in political orientations. These data are truly longitudinal and cover the years of life from ages 18 to approximately 50, making it possible to examine sources of attitudinal change over the course of an important and lengthy segment of the adult lifespan—a segment that includes the alleged change from idealistic 20-year-olds to coldly rational 30-year-olds that is the basis for so much folk wisdom and scholarly analysis. Still, we readily admit these data do not provide insight into changes in political orientations during later stages of the life cycle. These changes are undeniably important and should not be assumed to be merely a continuation of the nature and direction of changes occurring earlier.

As noted above, our operational theory combines the emphases of the political science tradition stressing stability in political beliefs across the lifespan with the tradition apparent in other disciplines stressing the existence of a conservative shift with age. We assert that stability in views will be quite common. This expectation is consistent with longstanding findings in political science, going back at least to Converse, as well as with more psychologically and biologically based assertions that people have relatively stable, politically relevant predispositions that are difficult but not impossible to change (Hibbing, Smith, and Alford 2014). At the same time, our theory recognizes that not everyone remains perfectly stable. Previous work on the nature of aging is convincing in suggesting that, for psychological and other reasons,

pressure toward the political right will be greater than toward the left. Therefore, we expect that on those occasions when stability is not in evidence individuals will be significantly more likely to become more conservative than more liberal.

To put it differently, consistent with a substantial amount of political science research, we predict that most people's political orientations in early adulthood will be accurate predictors of their orientations at least until late middle age but, consistent with folk wisdom and research in other disciplines, we expect that the movement occurring will not be balanced. Aging does entail conservatizing tendencies; it is just that these tendencies are usually not powerful enough to override inertial forces. As such, our model combines the known persistence of political beliefs with the conservatizing pressures believed to accompany the aging process (e.g., Sears and Funk 1999; Sears and Valentino 1997).

Testing these expectations could facilitate important advances in theoretical understanding of the nature and sources of political orientations. If a shift to the right with aging is detected, it would suggest that the next step for researchers will be sorting through each of the many features of aging that could be the reason for the conservatizing pattern. If, on the other hand, aging does not bring a shift to the right, this would suggest that the substantial theoretical bases for expecting such a relationship need to be reconsidered. What are the actual consequences of aging for the two conceptualizations of conservatism—over time stability in beliefs and embracing Burkean issue positions? Looking at this question from a cross-sectional perspective is useful but observing key variables unfold throughout the course of actual lives holds the promise of providing more revealing answers.

Moreover, the evidence is strong that on a range of important issues, such as attitudes toward the death penalty and corporal punishment as well as tolerance for inter-racial marriage,

females in non-traditional roles, and gay rights (Schwadel and Garneau 2014), public opinion as a whole has become more liberal in recent decades even as at any given point older people tend to have more conservative positions than younger people on these issues. What will happen if society's shift to the left on selected issues does not continue? If it is the aging process that produces conservatism, older people will continue to be more conservative than their younger colleagues. If, however, older people have not become more conservative with age but rather have merely continued to hold the beliefs they did when they were 20 years old—beliefs that decades later might appear to be conservative—then the apparent conservatizing effects of age would be misleading and older people would no longer appear to be more conservative. The question becomes whether, if society's drift to the left stopped, older people would eventually cease being more conservative than young people? We propose to determine whether the apparent tendency of aging to shift political beliefs to the right is largely due to the practice of confusing the effects of aging with the effects of age.

Aggregate Results

For our purposes, the key limitation of the MSS data is that only a few political items were posed to the student cohort and several of them offered very limited response options and/or were posed only in selected waves. The only seven-point item included in 1965 was party identification (1=strong Democrat; 7=strong Republican). Six additional seven-point items were posed in all of the waves except 1965: self-reported ideological identification (1=liberal; 7=conservatives), attitudes toward government assistance to minorities (1=in favor; 7=opposed), attitudes toward equality for women (1=in favor; 7=opposed), attitudes toward marijuana legalization (1=in favor; 7=opposed), attitudes toward jobs guaranteed by the government (1=in favor; 7=opposed), and attitudes toward the rights of the accused (1=in favor; 7=opposed).

Table 1 presents mean attitudes on all these measures for every time point they were assessed in the MSS. Reading these means from left-to-right within each row thus tracks how the average score on each trait's seven-point scale changed across time in the MSS sample. Table 1 also reports difference of means tests (two-tailed t-tests) indicating whether these attitudes showed any statistically significant change ($p < .05$) between time points. For example, in the first row of Table 1, we see a statistically significant difference between party ID in 1982 and 1973, and between 1997 and 1982.

(Table 1 about here)

At first blush, the MSS data seem to provide support for the belief that people tend to become more conservative with age. Reading across rows we see that six of the seven variables available for analysis shift significantly to the right as this cohort ages from 26 to 50 (and from 18 to 50 in the case of party identification, the one variable for which readings were taken in 1965). The one exception is attitudes toward equality for women which became significantly more favorable from age 26 in 1973 to age 50 in 1997 (a shift to the left of 1.05; for an explanation of why this issue may be different from the other variables, see Levendusky 2009). Typical movement to the right on the six variables is around a half-point on the 7-point scales, with a range from .35 on legalizing marijuana to .92 for providing rights for the accused.

In all cases the lion's share of this movement came between age 26 to 35 (that is from 1973 to 1982) rather than from age 35 to 50 (1982 to 1997). In fact, the only items for which there was a statistically significant shift to the right from age 35 to 50 was for party identification and self-reported ideological labels and the substantive movement in these cases was modest (.15 for party identification and .10 for ideology). From age 35 to 50, the MSS cohort did not become significantly more conservative on any of the five substantive 7-point issues included in

the surveys. Indeed, in this time period they became slightly more liberal on the role of women and rights of the accused. The fact that the overall drift toward conservatism is evident only between 1973 and 1982 raises the distinct possibility that this shift may be attributable to period rather than aging effects. For example, the 1982 reading took place in the context of the Reagan era when America seemed to be shifting to the right—though it is also the case that 1982 was not a particularly good year for Republicans: they lost 27 House seats in the mid-term elections and, owing largely to a recession, President Reagan’s popularity had dropped to 40%.

Be this as it may, the larger issue is that longitudinal data with a single cohort cannot separate aging from period effects (Firebaugh 1997; O’Brien 2011; Yang and Land 2013). Is the pattern of results presented in Table 1 due to a universal rhythm of aging or is it due to something unusual surrounding the period of time analyzed? In order to provide a partial answer to this question, we compare the MSS results with information on the changing climate of the times. More specifically, we present the attitudes of the MSS cohort alongside of the results of each of the ANES surveys conducted closest in time to the MSS data collection points, thereby making it possible to examine the degree to which the aging of the MSS sample is or is not consistent with mean attitudes of the country at about the same time as the MSS soundings were taken. We are able to perform this analysis for four of the measures included in Table 1: party identification, ideological identification, attitudes on women’s rights, and attitudes on minority assistance. The other three issues in Table 1 did not have equivalent ANES 7-point items included at the necessary time points.

(Table 2 about here)

In Panel A of Table 2, we compare the mean attitudes for the MSS cohort (see Table 1) with the mean for all ANES participants in the appropriate year. This practice makes it easier to

parse age and period effects given that the full ANES dataset allows us to establish the general change in attitudes across American society during the relevant timeframe. If MSS attitudes over the years merely move in sync with the full ANES data, it would be difficult to claim an independent effect for aging. If, on the other hand, they shift to the right more rapidly than does the national mood (as represented by the full ANES sample), the case that conservative orientations increase with aging is enhanced.

The pattern for each of the four available variables is somewhat different. With regard to party identification, the MSS sample was consistently more Republican than the nation as a whole but the gap does not appear to change much over the decades: In 1965, the MSS sample was .22 more Republican than the ANES sample and in 1997 it was .28 more Republican, so there is little evidence of an age-related rightward shift in relative PID. The case for such a shift is marginally better for ideological self-report. In 1973, when the MSS cohort was 26, it was significantly more liberal than the nation as a whole (3.78 to 4.14); by 1997, when the cohort was 50 it was no longer more (or less) liberal than the nation as a whole (4.33 to 4.33). Similar modest shifts to the right, relative to the national mood, occur for the two issue positions for which data are available. In 1973, the MSS sample was .44 more liberal than the full ANES sample on the issue of minority assistance; 24 years later it was only .30 more liberal. Similarly, the shift toward more liberal stances on women's equality between 1973 and 1997 was slightly less pronounced for the (aging) MSS sample (a drop of 1.05 from 2.99 to 1.94) than for the country as a whole (a drop of 1.27 from 3.51 to 2.24).

Looking across the four available measures in Panel A of Table 2, evidence for a conservatizing shift attributable to aging is modest. The aging of the MSS sample was accompanied by conservative shifts that were slightly greater (or in the case of attitudes toward

women's equality, by liberal shifts that were slightly less) than movements for the country as a whole. Differences in movement between the age-affected and age-unaffected samples, however, are typically only about .2 or .3 on a scale of 1 to 7.

We employed other variants of ANES data to provide baselines against which to compare attitudes of the MSS cohort and we present them in Panels B and C of Table 2. The first (Panel B) identifies those in the ANES dataset who were in the same age cohort as the MSS cohort at any given time. To be more specific, in Panel B we compare the familiar MSS results not with the full ANES sample, as we did in Panel A, but rather with only those ANES respondents who were between the ages of 21-29 in the 1974 ANES survey, 33-41 in the 1982 ANES survey, and 45-53 in the 1996 ANES survey. As such, these particular ANES respondents should reflect the age bracket into which the MSS respondents fell at each data point. Including this set of data has two advantages. First, it provides a validity check on the MSS cohort data (a large divergence between the two datasets might suggest an issue with the external validity of the MSS data). Second, differences in patterns of change between these two datasets could indicate generational effects. On the whole, the results look good for the MSS sample. Though occasionally (for 4 of the 13 pairs) significantly different from the comparable ANES age group at a comparable time, these differences are substantively quite modest and are as likely to be in a liberal as a conservative direction. More to the point, this comparison does little to strengthen the evidence of a connection between aging and conservatism.

In Panel C, we compare the MSS cohort with only the ANES respondents who were 21-29 years old, regardless of the survey year. Thus, as we move from 1973 to 1982 to 1997 the MSS sample becomes ever older than the baseline 21-29-year-old ANES subset, a situation that could provide some additional information on the effects of aging. If conservatizing movements

are being driven by aging, the gap between the MSS sample and the ANES “forever-young” subset should increase in the later data points (1982 and especially 1997) as the age gap grows.

As it turns out, this pattern is really only evident for ideological self-report for which no differences in the samples exist either in 1973 or 1982 but by 1997, when the MSS sample is 50 and the ANES subset is still in their 20s, the MSS cohort is significantly more conservative. For the other three variables, there is little change in the gap present in the early readings and the gap present in 1997.¹

Individual Level Results

Aggregated statistics can be misleading even when presented in the context of control groups, so we next examine individual-level patterns of change. In the interest of space, we do so only for one central variable of interest—ideological self-labeling—which was the lone variable for which it appeared a slight conservatizing tendency was present. We broke the seven-point scale of ideology into a three-point scale where liberals, including weak liberals, were one category, moderates were another category, and conservatives, including weak conservatives, were yet another category. We did this to make it possible to identify people who changed their ideological label from 1973 to 1997 as opposed to those who stayed the same (or moved in 1982 and came home in 1997). The results are broken down according to whether respondents in 1973 identified as liberals, moderates, or conservatives. They are presented in Table 3.

(Table 3 about here)

At least for ideology, the results seem to comport with our expectations that stability is the norm but that when movement does occur it will usually be in a conservative direction.

Forty-four percent of liberals stayed liberal, 48% of moderates stayed moderate, and fully two-

¹ Results comparing the MSS cohort to ANES respondents who attended college can be found in Table A.1 in the online appendix.

thirds of conservatives stayed conservative over the course of a quarter century, so stability is common. When movement does occur with age, the bias is toward a more conservative ideological posture. This is apparent both in moderates, where those moderates who did change were three times more likely to become conservatives than to become liberals as well as in the imbalance of ideological movement for liberals and conservatives: 34% of liberals at age 26 were conservatives at 50 but only 14% of conservatives at 26 were liberals at 50.

Growth-Mixture-Modeling Results

The previous section did not permit much in the way of systematic analysis of the nature of individual variation, focused only on one variable (self-reported ideology), and did not leverage model fitting. Therefore, we now utilize growth-mixture modeling (GMM)—a more sophisticated technique—to examine patterns of change across several of the political variables contained in the MSS data set. Growth-mixture modeling allows for the identification of latent classes based on patterns found in repeated measures (Ram and Grimm 2009). As each of the items was measured repeatedly in the MSS, it is possible to use growth-mixture modeling to identify patterns regarding both attitude stability and the direction of individual-level attitudinal change.

Though growth-mixture modeling can be an exploratory exercise, we take a confirmatory analytical approach. We begin with the assumption that there are five general patterns of “change” possible, though the first three patterns actually are patterns of stability; namely, some people will start off conservative and remain conservative, some people will start off moderate and remain moderate, and some people will start off liberal and remain liberal. The next two are patterns of lability: people who change in a conservative direction and people who change in a liberal direction. Essentially, what we did with the GMM is treat these as five latent classes for

each item, then tested to see whether models with fewer latent classes better fit the data. Specifically, we constrained the model to five latent classes for each item, and then we used the Vuong-Lo-Mendell-Rubin Likelihood Ratio Test (VLMR-LRT) to decide if the model was a better fit than a model with one fewer class. If the model was a better fit than the $K-1$ model ($p < .05$), we then selected that model. If the model was not a better fit, we then ran the $K-1$ model to see if the four-class model fit better than a three-class model. We continued this process until we found a model with a better fit than the model with one fewer class. We ran the analyses with MPlus version 7.1 (Muthén and Muthén 1998-2017).

(Table 4 about here)

Table 4 reports the estimates of the proportion of the MSS cohort that falls into each category in the best fitting model. So, to take the case of the guaranteed jobs item, what Table 4 shows is the best fitting model consisted of two categories, people who maintained a conservative viewpoint on this issue (about 77.5 percent of the cohort) and people who moved in a liberal direction on this issue (22.5 percent). While there is some variation from item to item, the overall pattern that emerges is that stability is more dominant than lability, with any shift more likely to be in a conservative direction. For example, on self-reported ideology (the first row of Table 4), roughly three-quarters of the MSS cohort is estimated to remain stable across the time span studied. Of the roughly 25 percent that did shift, about 21 percent moved in a conservative direction and only 4 percent in a liberal direction (the issue of guaranteed jobs is the big exception). In other words, the best fitting model suggests that if you started out conservative you stayed conservative (25 percent), if you started liberal you stayed liberal (16.5 percent), and if you started a moderate you stayed a moderate (33 percent).

On average, roughly 75 percent of the MSS cohort exhibited stable attitudes across the seven items we were able to analyze (bottom row of Table 4). Among those whose attitudes did shift, they were more than twice as likely to move in a conservative direction (17.4 percent), as opposed to a liberal (7 percent) direction). In sum, the more rigorous statistical analysis of individual-level patterns confirms the general aggregate patterns reported in Table 3.²

Conclusion

As a young man, George Babbitt, the eponymous protagonist of Sinclair Lewis's 1922 novel *Babbitt*, temporarily embraced a nonconformist, socially liberal lifestyle that included dabbling in leftist politics. After some time, Babbitt gravitated toward a more conservative life with an appropriately conservative wife and friends. Though initially Lewis's fictional account seems consistent with the "people become more conservative with age" folk tenet, there is more to the story. Babbitt was bred, born, and raised in a conservative, conformity-driven Midwestern world. His conservatism did indeed waver for a time in early adulthood but it could be said that, rather than being marked by a gradual migration to conservatism, in terms of political orientation and social lifestyle, Babbitt went out much as he came into adulthood—with only an ephemeral dalliance in between.

This general pattern of consistency with occasional, mild conservatizing tendencies on those fairly rare instances when stability is not complete summarizes the results of our more systematic investigation into political change over the course of a lifetime. Our utilization of the most representative long-term longitudinal political data set available, attention to the direction of change, comparison with ANES baseline groups, and application of growth-mixture modeling

² The latent class means and slopes for each issue attitude are reported in Table A.2 in the online appendix.

allow us to make a modest but important emendation to both folk wisdom and previous scholarly work.

Of course, important caveats apply to this study. Most obviously, though the MSS is an incredible resource, it has full readings from just one cohort (18-year-olds in 1965) and partial readings from a second. Might these results have been different if they had been based on a cohort that did not come of age in the middle of the tumultuous 1960s? Information on a wider range of issue attitudes might also lead to different conclusion. In addition, change could well occur after age 50, subsequent to when the final wave of the MSS occurred for the student cohort. We certainly cannot rule out any possibilities and, therefore, caution should be employed before generalizing these findings. The nearly contemporaneous ANES results we present provide important historical context but are no substitute for multiple longitudinal data sets covering the entirety of adulthood—but hoping for such data sets to magically spring into existence is beyond fanciful. We are thankful for those longitudinal data that are available.

We find some evidence of age-driven movement toward the right for ideological self-report. Any apparent conservatizing movement by the (aging) MSS cohort for party identification and for attitudes toward minority assistance was largely accounted for by changes in the national mood—and attitudes toward the role of women became more *liberal* with increasing age. Lacking ANES data on attitudes toward rights of the accused, guaranteed jobs, and the legalization of marijuana, we do not know whether the MSS cohort's movement to the right on these issues between ages 26 and 35 was also matched by societal changes, though the fact that this shift did not continue from ages 35 to 50 suggests this may well be the case. On the other hand, Tables 3 and 4 show that, of those who shifted ideologies, many more moved toward conservatism than liberalism. Given that the variable that changes most with aging is not party

identification or substantive issue stances but rather ideological self-labeling, one intriguing possibility is that aging may increase the likelihood of identifying as a conservative more than it leads people actually to be conservative (this might help explain, for example, why attitudes on the role of women moved leftward while overall ideological self-identification moved in the opposite direction). Scholars have known for some time that Americans tend to self-report being conservative even as many simultaneously endorse liberal issue positions (e.g., Ellis and Stimson 2012). We know of no evidence that the disjunction between operational and self-reported ideology increases with age but our results suggest there may be value in pursuing this possibility.

If those who are not liberal at 20 have no hearts and those who are not conservative at 30 have no brains, there are many people in this world without either hearts or brains. The nature of attitudinal change through the lifespan is more nuanced than conventional wisdom and previous scholarship suggests. Whether because of genetics (e.g., Alford, Funk, and Hibbing 2005), powerful early socialization (e.g., Easton and Dennis 1980; Hess and Torney 1967), or the impressionable nature of late adolescence and early adulthood (e.g., Alwin, Cohen, and Newcomb 1991), we find that existing political science research is correct in emphasizing the stability of political orientations over the course of the lifespan. Acknowledgement of this stability, however, should not be so complete as to blind us to the fact that, as is so often the case, folk wisdom contains a glimmer of truth.

Acknowledgements: We would like to thank the members of the University of Nebraska Political Behavior Reading Group for their incisive comments and numerous previous drafts of this paper. We would also like to thank Jacob Cheadle for discussions which vastly improved the methodological section of this paper. Conference discussants at MPSA and our anonymous reviewers also deserve our thanks for their incisive comments on earlier drafts.

Protect Rights of the Accused	.21677	.17006	-	.54491	.06826	.0449
Women's Role	-	.68521	.17241	.06118	.08120	<.001
Average	.36367	.27619	.11546	.17458	.07008	-

Cells represent the proportion of the sample classified into each latent class. Empty cells indicate the group was not represented in the best fitting model. *p*-values are derived from the Vuong-Lo-Mendell-Rubin Likelihood Ratio Test with *p*<.05 meaning the model fit better than a model with one fewer latent class.

APPENDIX

Table A.1 Political Attitudes Across Time: MSS/ANES Comparison (ANES COLLEGE ONLY)

Year	Party ID		Ideology		Minority Assistance		Women's Equality	
	MSS	ANES	MSS	ANES	MSS	ANES	MSS	ANES
1965	3.48	3.97*	--	--	--	--	--	--
1973	3.57	4.14*	3.78	3.97*	3.80	3.74	2.99	2.65*
1982	3.81	3.85	4.23	4.11	4.49	4.02*	2.20	2.18
1997	3.96	4.08	4.33	4.17 (p = .0523)	4.52	4.65	1.94	1.92

*Statistically significant difference ($p < .05$, two-tailed t-test) between samples at same time point
All variables are on a 1 (most liberal) to 7 (most conservative) scale
MSS=Michigan Youth Parent Socialization Study
ANES=American National Election Study, subjects who attended college

Table A.2: Issue Attitudes Latent Class Means and Slopes

Issue Attitude & Latent Class	Mean (s.e.) at Time 1	<i>p</i> -value of Mean	Slope (s.e.)	<i>p</i> -value of Slope
Ideology SC	5.05 (.297)	<.001	.207 (.062)	<.001
